A Coupled Discrete-Event and Motion Planning Methodology for Automated Safety Assessment in Construction Projects

Md Mahbubur Rahman, Triana Carmenate, Leonardo Bobadilla, Sebastian Zanlongo, Ali Mostafavi

Abstract—Collisions between moving machinery and human workers in construction job sites are one of the main sources of fatalities and accidents during the execution of construction projects. In this paper, we present a methodology to identify and assess construction project plan dangers before their execution. Our methodology has the following steps: 1) Plans are translated from a high-level activity graph to a discrete event simulation model; 2) Trajectories are simulated using sampling based and combinatorial motion planning algorithms; and 3) Safety scores and risk-based heatmaps are calculated based on the trajectories of moving equipment. Finally, we present an illustrative case study to demonstrate the usability of our model.

I. Introduction

Construction zones are a source of potential accidents which include a significant loss of lives every year due to struck-by accidents involving moving machinery and workers [1]. Recent data show that the percentage of struck-by accidents constituted 17.6% of fatalities and serious injuries among construction workers [3]. During construction planning activities, safety managers and construction engineers might not be aware of the potential dangers in a construction site. Most times activity sequences are planned to minimize project timelines without taking safety into consideration. Parallel activities are scheduled with multiple moving equipment (like trucks, cranes, excavators) on the jobsite, which increase the danger levels on a site. The following are two coupled phenomena that affect the level of safety hazards related to struck-by accidents in construction jobsites: (1) the sequence of activities and jobsite layout, and (2) the movement patterns of workers and equipment [6]. The layout of a construction jobsite affects the movement of equipment and workers within the jobsite. In addition, the movement patterns (trajectories) of the equipment and workers continuously evolve due to changes in the requirements of each construction task as well as the addition or removal of obstacles on the jobsite.

In one stream of research, different studies (e.g., [32]) have developed optimization-based methodologies for safety assessment of construction site layouts. In another stream of research, discrete event simulation has been adopted for construction planning [31]. The studies related to these streams of research have two main limitations in terms of their use in safety planning: (1) lack of consideration of the impact of the layout of construction jobsites on the spatio-temporal

M. Rahman, T. Carmenate, L. Bobadilla and S. Zanlongo are with the School of Computing and Information Sciences, Florida International University, Miami, FL, 33199, USA. A. Mostafavi is with the OHL School of Construction, Florida International University Miami, FL, 33199, USA. {mrahm025,tcarm002,szanl001}@fiu.edu,bobadilla@cs.fiu.edu,almostaf@fiu.edu

motion trajectories related to the workers and equipment, and (2) lack of consideration related to the dynamic changes in the layout of construction sites at different stages of a project schedule. A key missing element in the existing body of knowledge and practice is a methodology that enables automated predictive assessment of struck-by hazards based on an integrated evaluation of the construction site layout, dynamic motion trajectories of workers and equipment, and the sequence of construction activities. Using predictive assessment, jobsite layout and sequence of activities could be evaluated during the planning phase to identify the safest plan and identify the hazardous zones in a construction jobsite. Hence, construction plans can be evaluated in terms of their safety hazards, and thus, potential hazards can be proactively eliminated through better planning. To address this gap, we propose a novel methodology that extends the existing construction simulation frameworks (mainly based on discrete event simulation) to incorporate motion planning algorithms to facilitate consideration of spatio-temporal characteristics of construction jobsites. Using our proposed methodology, construction plans could be evaluated and modified with respect to the likelihood of struck-by hazards.

Our ideas are connected to approaches that use Linear Temporal Logic, [5], [9], [11], [21], [22], [10], to create high-level specifications that can be translated to low-level trajectories. It also share commonalities with STRIPS-like representations [12] that connect with motion planning algorithms [8]. In contrast with these approaches, we used two representations commonly used in construction planning: Activity Graphs and Discrete Event Simulations instead of Logic Based representations such as LTL or PDDL. This will allow us to evaluate our methodology in existing construction plans and will help close the gap between high-level plans and state trajectories.

Some attempts have been made in the construction community to incorporate planning algorithms in the analysis of projects. Motion planning has been used to analyze crane motions and their safe operations. In [38], [13] and [40] a modification of the RRT algorithm for replanning of crane motions was used in real time along with positioning systems for simulation and safety purposes. However, these tools are intended only to capture a small part of the activities in a construction project. Attempts have also been made to use logic based algorithms for automatic plan generation [18].

In this paper we focused on calculating the safety score for different construction plans and selecting the optimal plan. Different models are used to simulate the construction activities [4], [39], [16]). However these tools are intended

only to capture a small part of the activities and some of them only provide graphical modeling [16]. We developed an automated system that can help planners to realize the safety level of the planned activities at discrete times of a construction project at the pre-planning phase. These ideas can help managers re-plan a sequence of activities in order to reduce the chance of fatalities and injuries during a construction project.

To our best knowledge, our approach is one of the first to consider to use motion planning techniques to evaluate the safety scores or determine obstacle free trajectories for workers and moving equipment. The concrete contribution of our work are the followings: 1) We generate a number of alternate construction plans rather than the one that gives the minimum project completion time; 2) We developed an activity and event scheduler to simulate all the plans using discrete event simulation and motion planning. A number of trajectories are generated and coordinated to avoid collisions; 3) We decompose the layout of a construction site into a grid to calculate the safety score. This enables us to generate heatmaps of the construction layout to identify dangerous hotspots of a site at discrete times.

The rest of the paper is organized as follows: Section III presents the preliminaries and the problem formulation. Section III introduces algorithms to transform a construction plan to a discrete event model. Then activities are scheduled using a discrete event scheduler and safety is calculated for the construction site. Section IV presents an illustrative case study of a construction site. Finally, conclusions and directions for further research are discussed in Section V.

II. PRELIMINARIES

A. Activity Graph

The Critical Path Method(CPM) [29] is widely used in construction projects to determine the minimum amount of time needed to complete a project. An activity graph is a type of CPM with no timing information. The activity graph, $\mathcal{G} = (\mathcal{V}, \mathcal{E})$, is a directed acyclic graph. An edge, $e \in \mathcal{E}$, where $e = v \to v'$; $v, v' \in \mathcal{V}$ is formed if and only if v is a precondition of v'. It is helpful to consider v as a parent of v'. The starting node set, $\mathcal{V}_s \subset \mathcal{V}$, is a collection of nodes who have no incoming edges. Similarly, every node in the set of finish nodes, $\mathcal{V}_f \subset \mathcal{V}$, have no outgoing edges. A sequence of all nodes, \mathcal{P} , conserving precedence constraints form a construction plan. It is possible to generate different construction plans from an activity graph.

B. Construction Physical State Space

Assume that a construction project takes place in a 2D world, $\mathcal{W} = \mathbb{R}^2$. A nonempty set of *physical system state spaces* can be represented as, $X = X^1 \times X^2 \times \ldots, X^{\iota}$, which is a finite or countably infinite set of *states*. The set of a number of initial static obstacles is, $\mathcal{O}(t) \subset \mathcal{W}$ where the obstacle list, $\mathcal{O}(t)$, is a time variant dynamic list, since new obstacles may appear and old obstacles may disappear as the construction project goes on. A construction project has a set of time constrained objectives which are considered

individual sub-components. To realize the abstraction of discretization, we define an index set, $\mathcal{I} = \{1, 2, \dots, \iota\}$. A sub index is defined for an activity, v, as $\mathcal{I}_v \subset \mathcal{I}$. Thus the system state is divided into a number of sub-states, $X = \times X^j$ where $j \in \mathcal{I}_v$ and each set, $X^j \subset X$, is assigned to some individual activity or node, $v \in \mathcal{V}$, in the planning graph.

A system state, $x^j \in X^j$, is composed of a number of parameters to describe a subproblem. The parameters in x^j can be configurations, orientations and velocities of moving bodies (such as trucks or cranes) as well as the amount of resources used by an activity.

A *time* attribute has to be introduced in order to aid the scheduling of activities properly in a time varying discrete event system. The *time varying state space* is the cartesian product $Z = X \times T$ and a state, $z \in Z$, is denoted as z = (x,t). There are a number of moving bodies/equipment in the system represented by the set, $\mathcal{B}(x)$. Considering both the moving bodies and static obstacles, the obstacle state space is defined as,

$$Z_{obs} = \{(x, t) \in Z | \mathcal{B}(x) \cap \mathcal{O}(t) \neq \emptyset\}$$
 (1)

and the free space is defined as, $Z_{free} = Z \setminus Z_{obs}$. An *initial* state is defined as, $z_I \in Z_{free}$ and the set of goal states is defined as, $Z_G \subset Z_{free}$:

$$Z_G = \{(x, t) \in Z | x \in X_G, t \in T\}$$
 (2)

A state time space, Z^v , is assigned to an activity, v, where $Z^v = X^v \times T$. A particular time varying configuration, $z^v \in Z^v$, of a sub problem is $z^v = (x^v, t)$. After simulating all the nodes, $v_i \in \mathcal{V}$, in a plan we generate a set of trajectories, $\widetilde{Z}[0,1] \to Z_{free}$ by coupling discrete event simulations with low level motion planning techniques.

C. Augmented Discrete Event System Specification

Each node of a high-level construction plan in an *activity graph* is represented as an *Augmented Discrete Event System Specification (DEVS)* [37] model. This model is used along with geometric information frem the construction site to generate obstacle free paths and policies for moving bodies. Each node in the *activity graph* is associated with an augmented DEVS model.

The DEVS formalism proposed by [37] and detailed in [35] and [34] is used to formalize discrete event simulation as an extension of finite state automata. An event scheduling model is a tuple ES^v for the activity $v \in V$ and is represented as:

$$ES^{v} = (E^{v}, Z^{v}, EL^{v}, f_{n}^{v}, f_{z}^{v}, z_{I}), \tag{3}$$

where $Z^v = X^v \times T$ is the subset of the states of the system. Any activity in a construction site consists of a set of events. The i^{th} event is denoted by η_i and if there are ξ unique events, we define the finite event set as, $E^v = \{\eta_1, \eta_2, \ldots, \eta_{\xi}\}$. The event list EL^v is defined by $EL^v = \{(\eta_1, t_1), (\eta_2, t_2), \ldots\}$.

The system starts at time t_0^v with starting state, z_I . The system state is modified based on the current state and an event of an activity:

$$f_z^v: Z^v \times E^v \to Z^v. \tag{4}$$

In some cases f_z^v is controlled by the availability of resources (for example the amount of soil that needs to be excavated) and system time. The next event to be scheduled is controlled by f_n^v , based on the current event and system state:

$$f_{\eta}^{v}: E^{v} \times Z^{v} \to E^{v}. \tag{5}$$

An activity is finished when the event list, EL^v , becomes empty and we schedule the next activity. Then we need to extract the collision free trajectories in Z_{free} space knowing initial and goal configurations in X space.

Problem 1: Generation of collision free trajectories $\widetilde{Z}[0,1] \to Z_{free}$ for moving equipment through multilevel evaluations

Given an initial configuration, x_I , a set of goal states , X_G , and the set of static obstacles, $\mathcal{O}(t)$ at time, t, find a collision free trajectory, $\widetilde{Z}[0,1]$, such that $\widetilde{Z}(0) = z_I$ and $\widetilde{Z}(1) \in Z_G$.

D. Safety Evaluation for Different Plans

A safety score is associated to every node in a particular construction plan, $\mathcal{P}=(v_s,v_2,v_3,\ldots,v_f)$. To calculate the safety score for individual plans, we evaluate the entire plan by simulating all the nodes. A safety score is defined as a function,

$$R: \widetilde{Z} \to [0, 1], \tag{6}$$

where \widetilde{Z} is the set of all trajectories, 0 is the safest score and 1 is the most dangerous score for a plan. Therefore we can calculate the safety score for a plan based on the trajectory paths.

Problem 2: Safety Evaluation

Given a set of time variant system trajectories, \widetilde{Z} , calculate a safety score for the plan, \mathcal{P} , in the closed interval range [0,1].

Once the safety score is calculated for the alternate plans we need to extract the optimal one which provides minimal completion times and optimal safety scores.

Problem 3: Mulicriteria Optimization Problem

Given a number of safety scores for several plans $\mathcal{P}_1, \mathcal{P}_2 \dots \mathcal{P}_i$, calculate the optimal plan which minimizes the project's finishing time while optimizing the safety score.

III. METHODS

A construction plan starts with a 2D layout of the construction site. An example site layout is shown in Figure 1, where a construction plan is needed to carry out two excavation activities in *Building1* and *Building2* followed by concrete pouring activities. The system block diagram of our model to extract the safest plan is shown in Figure 2. An activity scheduler subsystem is responsible for generating alternate sequence of activities. It communicates with the event scheduler subsystem to simulate one or a number of activities depending on simultaneous scheduling. The event scheduler uses motion planning algorithms to generate paths for the moving bodies and a coordinator calculates a way to schedule them without colliding with the bodies of other activities.

The obstacles whether moving or static, have a different impact on the safety of the construction plan. Also, different

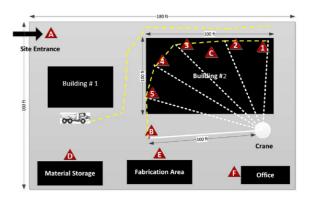

Fig. 1. An example layout of a construction site. Excavation and concrete pouring need to be done in two buildings. Yellow dotted lines are trajectories of moving truck and crane's hook.

sequences of plans yield different safety scores. Therefore, we need to evaluate all the alternative plans.

Definition 3.1: Moving equipment, \mathcal{B} , do not affect the safety of two sequential activities. The moving equipment, \mathcal{B}^u and \mathcal{B}^v of two parallel activities, u and v, affect the safety of one another.

Definition 3.2: Static obstacles, \mathcal{O}^u , generated by an activity, u, have a succeeding effect on the safety score of all the successor activities, $v \in \mathcal{V}$, unless the obstacle built earlier is removed by some later activity.

Proposition 3.3: Different plans yield different safety scores.

Proof: Suppose we have two alternate plans, \mathcal{P}_1 and \mathcal{P}_2 , from a graph, \mathcal{G} . We choose two activities, u and v, where in plan \mathcal{P}_1 , u is scheduled before v, and in plan \mathcal{P}_2 , v is scheduled before u. By definition 3.1 their safety score is the same. However by definition 3.2 if the static obstacles generated by u and v are not same, then the plans yield different safety scores.

A. Plan Extraction from an Activity Graph

A topological sorting algorithm is used to extract all possible valid plans. Given n vertices, and a set of integer index pairs, (i,j), of the nodes of the graph, \mathcal{G} , where $1 \leq i, j \leq n$, the problem of topological sorting is to find a permutation v_1, v_2, \ldots, v_n such that i appears to the left of j for all pairs (i,j) [20]. Two algorithms, [20] and [36], are used to generate all such arrangements of vertices. We have used the latter one here.

There is more than one start and finish activity. Two dummy activities, v_s and v_f , are added to the graph as starting and final activities with a duration zero in order to create single starting and finishing points for the plan(nodes S and F in Figure 3). By default v_s is labeled as Visited and is the parent of all initial nodes, $\mathcal{V}_s \subset \mathcal{V}$, while v_f is the child of all the finishing activities, $\mathcal{V}_f \subset \mathcal{V}$.

Given \mathcal{P} , produced by the topological sorting algorithm, Algorithm 1 is used for scheduling the activities inside \mathcal{P} . A queue, Q, is initialized to hold the active (not yet scheduled/visited) activities in Line 1. Line 2 starts a for loop to go over all the activities $u \in \mathcal{P}$ starting from index 1 (remember activity 0 is the dummy starting activity). Line 4 uses the ParentVisited() function to check whether all the parents of

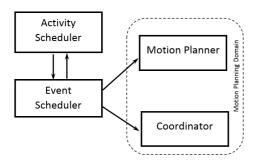

Fig. 2. System submodel interaction

the current activity have been scheduled. If not, the activities in Q are scheduled by calling the EventSchedule(Q) routine. It guarantees scheduling all parent nodes of the current node, because the nodes in $\mathcal P$ are organized in topological order. The corresponding activity nodes are all set as Visited from lines 6 to 8. Q is flushed at line 9 to load the current activity. At line 11, the current activity node is loaded into Q, whose parent nodes have already been scheduled.

Algorithm 1 ActivityScheduler(P)

```
1: Q \leftarrow \emptyset
 2: for i = 1 to |\mathcal{P}| do
        u \leftarrow \mathcal{P}[i]
 3:
        if \neg u.ParentsVisited() then
 4:
            EventScheduler(Q)
           for all v \in Q do
 6:
 7:
               v.Visited \leftarrow true
 8:
           end for
           Q \leftarrow \emptyset
 9.
        end if
10:
        Q.Insert(u)
11:
12:
    end for
```

B. Event Scheduling Using Augmented DEVS

Each node in a plan needs to be evaluated through our event simulation method. A queue of activities is received from the ActivityScheduler routine. Each activity is a collection of events, $\eta \in E$. All of the events in E are motion planning problems which have to be solved before going on to the next event. Algorithm 2 is used to simulate a number of nodes in the activity graph using our augmented DEVS model. In order to carry out the simulation in line 2, we first create an event scheduling model, ES, as defined earlier, for each node. Line 3 extracts the initial state, $z_v \in Z^v$ and line 4 takes the first event from the event set to populate the empty event list. The while loop in line 6 is used for scheduling all the events from multiple activities. The min method in line 8 helps to extract the immediate event's time from the event list to be scheduled if more than one event is in the list. Consequently, line 9 provides the next event. The MotionPlanner() routine in line 10 generates a number of trajectories, $(\tilde{x}_1, \tilde{x}_2, \dots, \tilde{x}_{|Q|})$, each of which contains a sequence of configurations.

Line 12 calls the Coordination() routine to generate a set of collision free time variant trajectories, $(\tilde{z}_1, \tilde{z}_2, \ldots, \tilde{z}_{|Q|})$, for each activity. Lines 13-16 are the updating steps of the

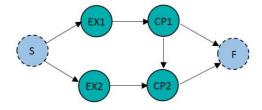

Fig. 3. An example activity graph of a construction site.

system states. On line 14 a new system state, z_v , is calculated based on a current state and event. State z_v keeps track of the *resources*, *configurations*, etc of moving bodies for each of the events along with other information. If $z_v \in Z_G$, then the function f_η in line 15 will generate a Null event. The routine stops when no activity generates any event other than Null.

Algorithm 2 EventScheduler(Q)

```
1: for all v \in Q do
             ES^v \leftarrow CreateDEVS(v)
             z_v \leftarrow initial \ state \in ES^{\acute{v}}
 3:
            EL_v \leftarrow ((\eta_1^v, 0) : \eta_1^v \in E^v)
 4:
 5: end for
       while [(EL_1 \neq \emptyset) \lor (EL_2 \neq \emptyset) \lor \cdots \lor (EL_{|Q|} \neq \emptyset)] do
            for all v \in Q do
 7:
 8:
                  t^v \leftarrow min\{t: (\eta, t) \in EL^v\}
                 \begin{array}{l} \eta^v \leftarrow \{\eta: t^v \in (\eta, t)\} \\ \tilde{x}_v \leftarrow MotionPlanner(\eta^v, z_v) \end{array}
 9:
10:
11:
             (\tilde{z}_1, \tilde{z}_2, \dots, \tilde{z}_{|Q|}) \leftarrow Coordination(\tilde{x}_1, \tilde{x}_2, \dots, \tilde{x}_{|Q|})  for all v \in Q do
12:
13:
                 z_v \leftarrow f_z^v(\eta, z_v) 
 \eta_{new}^* \leftarrow f_\eta^v(\eta, z_v) 
 EL_v \leftarrow (EL_v \setminus (\eta, t)) \cup (\eta_{new}^*, t + \tilde{z}_v.t)
14:
15:
16:
            end for
17:
18: end while
```

C. Motion Planner

The MotionPlanner() routine called in Line 10 of the EventScheduler() routine works based on existing motion planning algorithms. Sampling based algorithms like RRT [27] or PRM [19] can be applied to calculate the trajectories, \tilde{x} , of the moving equipment. Also, RRT* [17], an optimized version of RRT, can be applied to generate a better path than a non-optimized RRT. If the planning domain is low dimensional (i.e, a 2D domain) then certain combinatorial planning algorithms, like $trapezoidal\ decomposition\ [23]$, can be applied to achieve an efficient path. If an event in an activity has no motion, then the trajectory is a simple point in the configuration space, X [24].

D. Coordination Space

The sequence of trajectories, $\tilde{x}_1, \tilde{x}_2, \ldots, \tilde{x}_{|Q|}$, each of which is formed by a sequence of configurations, is generated by the motion planner for each activity regardless of whether they collide or not with the bodies of the other activities which may run in parallel. Hence, the bodies following the trajectories may collide with the bodies of other parallel

activities. Given m moving bodies, an m-dimensional coordination space, $\Gamma = [0,1]^m$, is represented as a unit cube to schedule collision free paths for the moving equipment [26]. The i^{th} coordinate of Γ represents the domain, $\Gamma_i = [0,1]$, of the path \tilde{x}_i . Let γ_i denote a point in Γ_i . The pairwise robotrobot(body-body) obstacle region is, $\Gamma^{ij}_{obs} = \{(\gamma_1,\ldots,\gamma_m) \in \Gamma | \mathcal{B}^i(\tilde{x}_i(\gamma_i)) \cap \mathcal{B}^j(\tilde{x}_j(\gamma_j)) \neq \emptyset\}$ which is combined to yield $\Gamma_{obs} = \bigcup_{i,j} \prod_{i \neq j}^{ij} \Gamma^{ij}_{obs}$. Therefore, $\Gamma_{free} = \Gamma \setminus \Gamma_{obs}$.

At state $(0,0,\ldots,0)\in\Gamma$, all bodies are in their initial configurations, $x_i=\tilde{x}(0)$, and at state $(1,1,\ldots,1)\in\Gamma$, all bodies are in their goal configurations. Any continuous path, $h:[0,1]\to\Gamma_{free}$, for which $h(0)=(0,0,\ldots,0)$ and $h(1)=(1,1,\ldots,1)$ moves the bodies to their goal configurations [24]. We applied the A^* search algorithm [33] on Γ to generate a path h avoiding robot-robot collisions. Moving diagonally along h in Γ moves all three bodies whose relative speeds depend on the slope of the path. A body is allowed to move with a constant speed or directed to remain stopped to yield the other bodies to pass by moving horizontally or vertically in Γ [24].

E. Safety Model

We decompose the workspace, \mathcal{W} into a grid by δ number of squares. A safety score is computed for each square. Together the safety scores of all the squares at a time, t, contribute to the risk of the plan at that time. Once we know the number of moving bodies for each activity in an activity graph and their trajectories, we have all the data necessary to evaluate the safety for the different construction plans. We consider a construction boundary to be a perfect rectangular area. If it is not perfect, we can approximate it with a bounding rectangle and make the area not in the original construction layout into a static obstacle. The safety score for a square is highly dynamic as the construction jobsite frequently changes. It is inversely proportional to its distance to the moving equipment. For static obstacles, the squares outside of the obstacle region are not affected.

Assume that the duration of a plan, \mathcal{P} , is T where T is divided into a number of discrete time points $\mathcal{T} = \{0, \Delta t, 2\Delta t, \ldots, j\Delta t\}$ with fixed time intervals, Δt , such as $j = \frac{T}{\Delta t}$. We calculate the safety scores in discrete times of \mathcal{T} . Let $R(g_i,t)$ denote the score for square i of the grid at time, t. Then the definition of $R(g_i,t)$ is,

$$R(g_i, t) = \sum_{j=0}^{|Q_t|} \sum_{k=0}^{|B_j|} \frac{\alpha}{d(g_i, B_k(t)) + \beta},$$
 (7)

where d(.,.) is a distance function (such as the *Euclidean Distance*) and Q_t is the queue of activities at time t. Parameters α and β are the scaling factors for a better score. The safety scores for the squares inside the obstacles (static or dynamic) are,

$$R(g_i, t) = 1. (8)$$

Earlier we defined 0 as being the safest score in a plan and 1 as the most dangerous score for a plan. The average safety score, $r_{arid}: t \rightarrow [0,1]$, for a grid with δ squares at time t

ic

$$r_{grid}(t) = \frac{\sum_{i=0}^{\delta} R(g_i, t)}{\delta}.$$
 (9)

Therefore the total safety score r_{tot} for a particular activity plan, \mathcal{P} , averaged over \mathcal{T} is,

$$r_{tot} = \frac{1}{|\mathcal{T}|} \sum_{t=0}^{|\mathcal{T}|} r_{grid}(t). \tag{10}$$

We also calculate aggregated safety score over a time interval, $[t_i, t_f]$ where $t_i, t_f \in \mathcal{T}$. The safety score $r_{agg}(g_i)$ for a square g_i then is,

$$r_{agg}(g_i) = \frac{\sum_{t=t_i}^{t_f} R(g_i, t)}{t_f - t_i}.$$
 (11)

F. Optimal Planning Model

The safest plan is a partially ordered sequential plan. But this plan may make a construction project too lengthy, which is undesirable for the project stakeholders. Therefore, we need a plan which optimizes both the risks and finishing times by using task parallelism. This tradeoff between time and safety leads to a well-known *Pareto Optimization* [15] problem. Exact solutions for multicriteria optimizations are NP-hard [7], so we apply some heuristics to produce an approximate solution. Our activity scheduler schedules two or more activities simultaneously whenever possible in order to minimize project completion times. The safety model then calculates the safety score over discrete time points. The acceptance of a plan, therefore is decided based on the following criterion:

- Average safety $score(\mu)$ of a $site(\mu = r_{tot} \text{ from (10)})$.
- Standard deviation(σ) of r_{grid} over time.

If μ and σ both are low, this yields a very safe plan. If μ is low but σ is high, this is an acceptable plan. A plan with high values of μ and low values of σ is a very risky plan. Plans with high values of μ and high values of σ are also risky. For projects with deadline constraints, project managers can choose a higher safety score *threshold*. Below that *threshold* a plan with high parallel activities is acceptable. If a planning manager wants to choose a specific period to be safer than the other, episodic safety scores during a specific interval using (11) can be computed.

IV. CASE STUDY

We need excavation (EX) and concrete pouring (CP) activities done for two building sites, Building1 and Building2 in Figure 1. EX1 and CP1 in the activity graph of Figure 3 denote the excavation and concrete pouring activities in building1 and vice versa. Nodes S and F are the dummy nodes to hold starting and final points. EX1 and EX2 are two starting activities. CP1 depends on EX1 while CP2 depends on EX2 and CP1.

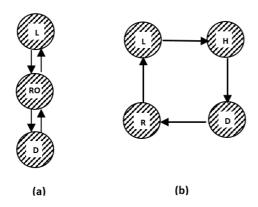

Fig. 4. (a) DEVS state transition model for the crane. (b) DEVS state transition model for the truck.

A. Alternative Plans

We used the Python programming language to implement a topological sorting algorithm as proposed in [36]. The following are three alternate plans for the activity graph of Figure 3:

 $\mathcal{P}_1 = [EX1, CP1, EX2, CP2]$ $\mathcal{P}_2 = [EX1, EX2, CP1, CP2]$ $\mathcal{P}_3 = [EX2, EX1, CP1, CP2]$

B. Activity Scheduling

For the plan, $\mathcal{P}_1 = [EX1, CP1, EX2, CP2]$, the Activity Scheduler routine in Algorithm 1 loads EX1 in Q as its parent, the dummy starting node S, is Visited. During the second iteration of the algorithm's loop it tries to load CP1 whose precondition activity, EX1, is still not Visited. So EX1 is scheduled using Algorithm 2. Once the scheduling is done, EX1 is marked as Visited and CP1 is loaded into Q. EX2 is also loaded in the next iteration, since its parent S has been Visited. CP2 is not loaded since EX2 has not been Visited. So, the two activities in the queue (CP1, EX2) are simulated simultaneously using the event scheduler. In the final run CP2 is simulated.

For the plan, $\mathcal{P}_2 = [EX1, EX2, CP1, CP2]$, the activities (EX1, EX2) are loaded first into Q and simulated together. Then (CP1, CP2) are simulated. The plan, $\mathcal{P}_3 = [EX2, EX1, CP1, CP2]$, can be simulated in a similar way.

C. Discrete Event Scheduling

A Python program with SimPy simulation module [2] was used to simulate the discrete event scheduler of Algorithm 2. An event scheduling model, $ES = \{E, Z, EL, f_{\eta}, f_z, z_I\}$, for each activity is created. For example, in Figure 4(a) there are three possible repeating events shown for the crane in charge of concrete pouring(CP). These are Load(L), Rotate(RO) and Dump(D). For excavation(EX), shown in Figure 4(b), a dump truck in charge of carrying soil has four such states: Load(L), Haul(H), Dump(D) and Return(R).

• Therefore, the set of events for concrete pouring is $E^{CP} = \{L, RO, D\}$ and the set of events for excavation is $E^{EX} = \{L, H, D, R\}$.

- The state, Z, contains the configuration of all parameters such as *resources*, *interruption*, *deadline*, etc.
- The configuration of the dump truck is R² ×S¹ while the configuration for the *non-holonomic* [28] crane is RP² as it can rotate with *pitch* and *yaw*, but no *roll*.
- An example state we use for the truck is, $z=(x_{tr},y_{tr},\eta_{tr},\theta_{tr},r_{ex},t_{ex})$, and an example state we use for the crane is, $z=(\theta_{cr}^{pitch},\eta_{cr},\theta_{cr}^{yaw},r_{cp},t_{cp})$.
- An example event transition for the dump truck is, $f_{\eta}^{EX}(L,z) = H$, as hauling is carried out after loading. Similarly, the crane starts rotating once it is loaded with concrete, $f_{\eta}^{CP}(L,z) = RO$ (See Figure 4).
- An example state transition for an excavation is, $f_z^{EX}(L,z) = (X_{tr}^{ex}, H, r_{ex} r', t_{ex} + t')$. The constant, $r' \in \mathbb{N}$, denotes the units of soil/resources consumed per iteration and $t' \in \mathbb{R}^{>0}$ is calculated from a *Coordination* function as described previously.

D. Motion Planning and Coordination

We used the Motion Strategy Library (MSL) [14] to generate trajectories of moving equipment for different activities(See Figure 5(a)). Two trucks, colored red and green, from simultaneous activities (EX1, EX2) are shown moving around the two building sites in Figure 5(a). Sample trajectories, \tilde{x}_1, \tilde{x}_2 (colored blue and green), of the trucks are shown in Figure 5(b). Trucks have differential constraints. Suppose the speed of the truck and steering angle is specified by the actions u_s and u_ϕ respectively. The transition equation for two consecutive configurations is, $\dot{x}_{tr} = u_s \cos \theta_{tr}, \ \dot{y}_{tr} = u_s \sin \theta_{tr}, \ \dot{\theta}_{tr} = \frac{u_s}{L} \tan u_\phi$ [25]. L is the length of the truck.

The red trajectory in Figure 5(b) is the path of a moving worker. We used a *maximum clearance roadmap* to calculate the trajectories of moving workers in a construction jobsite. *Generalized voronoi diagrams* were used in our previous work [30] to calculate the safest paths for workers while avoiding static obstacles. So we added a worker trajectory from a *Voronoi diagram roadmap* for a moving worker to create a three robot problem. Trajectory for crane's hook was generated by taking the arc of a circle centered at the base of the crane that goes through the initial and goal configurations of the hook.

The coordination space for the three moving bodies is shown in Figure 6. For better visual understanding we present

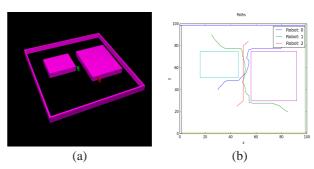

Fig. 5. (a) Two trucks in MSL library colored red and green moving around pink excavation areas (b) Trajectories generated by the MSL library (blue and green). Red trajectory was added to simulate moving worker.

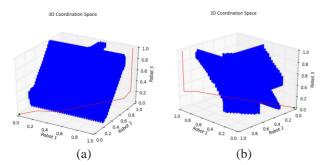

Fig. 6. Coordination space for robots from two different viewing angle. Blue regions are obstacle areas Γ_{obs}

the 3D image from two different viewing angles. Blue regions comprise collision configurations, Γ_{obs} , for three possible combinations of truck1-truck2, truck1-worker and truck2-worker. The continuous red path, h, is computed using an A^* search algorithm which connects the point from the initial configuration, (0,0,0), to the goal configuration, (1,1,1). For example two consecutive configurations (0.1,0.5,0.15) and (0.12,0.5,0.2) along the path, h, explain that the second body has stopped, letting the other bodies pass.

E. Safety Evaluation

It was mentioned earlier that the construction site is decomposed into a grid to calculate the safety score for individual squares in the grid. A safety score for each square was calculated in the range [0,1] using equations (7) and (8). Sample heatmaps were generated for the parallel activities (EX1, EX2) at different times where two dump trucks are moving as shown in Figure 7. The green colored regions are the safest and red regions are the most dangerous. Other colors, ranging from green to red, were applied based on safety scores. The heatmaps give construction planning

managers a detailed representation about the construction jobsite risks (i.e, the hotspots on the heatmaps) at discrete times.

Heatmaps based on aggregated safety scores(using 11) are shown in Figure 8 for four different sub-activities: EX1, CP1EX2, CP1CP2 and CP2. Aggregated scores, r_{agg} , for individual squares are calculated using (11) to give a concise episodic risk visualization in different areas of the construction site.

F. Optimal Plan Extraction

Two plans, \mathcal{P}_1 and \mathcal{P}_2 , were evaluated and the following table is the result of the averages and standard deviations of safety scores for the entire life of the construction plan.

Plan	μ	σ
\mathcal{P}_1	0.16	0.024
\mathcal{P}_2	0.17	0.014

According to our heuristics from section III-F, \mathcal{P}_1 is the better plan as it has low average and standard deviation values compared to plan, \mathcal{P}_2 . But using the heatmaps and aggregated scores, r_{agg} , the planning manager can choose alternative plans based on the construction project requirements. He also can then take into account the partial safety scores and the safety scores at a grid level granularity. If the project has a tight deadline, then the safety threshold can be used for acceptable results.

V. CONCLUSIONS AND FUTURE WORK

In this work, we developed an easily implementable methodology to minimize the risk of struck-by accidents in construction jobsites. Given an initial activity graph, our model extracts different sequences of activities, converts them to discrete event models and simulate them using discrete event scheduler algorithms. Motion planning methodologies

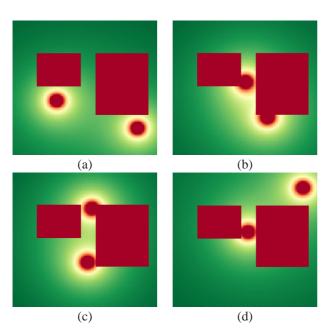

Fig. 7. Sample heatmap snapshots/frames during time (a) t=0; (b) t=74; (c) t=125; (d) t=226.

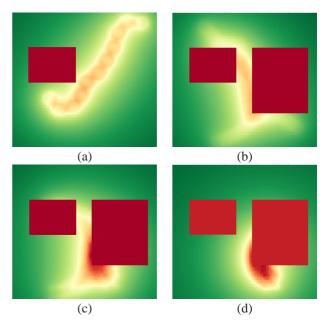

Fig. 8. Aggregated heatmaps (using 11) for the activities (a) EX1; (b) CP1EX2; (c) CP1CP2; (d) CP2.

generate the collision free trajectories for the moving bodies. A proactive safety visualization is provided during preplanning phase using heatmaps which effectively distinguishes among the safe and dangerous places in a construction site.

The model presented can be used for most construction activities to carry out simulation and safety metrics together. The formalism presented in the paper provides measurement metrics to construction project managers, such as safety scores and time spent by a trajectory. Based on this measure, the safety policy and guidelines can be calculated for workers in a construction site.

The proposed methodology is a first step towards improving of existing discrete event and motion planning approaches for automated investigation of struck-by safety hazards on construction jobsites. One immediate extension of our work is to take into account the stochastic nature of construction jobsites. We assumed that the motions performed by the moving obstacles were deterministic, so in the future we plan to incorporate models that include bounded and probabilistic uncertainty.

The results of our computations are plans for workers and moving equipment, and time indexed risk scores. We would like to closely study deployments linked with real-time monitoring of construction activities to evaluate how likely it is for a worker to follow a suggested plan and what alternate action spaces for workers can be used.

In this paper, we evaluated two commonly performed construction tasks: excavation and concrete pouring. We will extend this work to evaluate our methodology using information for larger construction projects involving different activities with large equipment fleets and a large number of workers.

VI. ACKNOWLDEGEMENTS

We would like to thank Mr. Winston Newman and the loss prevention team at Balfour Beatty Construction Company for their valuable feedback on the ideas presented in the paper.
